Abstract. Which factors shape the commercialization of academic scientific discoveries via startup formation? Prior literature has identified several contributing factors but does not address the fundamental problem that the commercial potential of a nascent discovery is generally unobserved, which potentially confounds inference. We construct a sample of approximately 20,000 “twin” scientific articles, which allows us to hold constant differences in the nature of the advance and more precisely examine characteristics that predict startup commercialization. In this framework, several commonly accepted factors appear not to influence commercialization. However, we find that teams of academic scientists whose former collaborators include “star” serial entrepreneurs are much more likely to commercialize their own discoveries via startups, as are more interdisciplinary teams of scientists.

Keywords: university technology transfer • entrepreneurship • technology commercialization • “twin” scientific discoveries

1. Introduction and Motivation

The technologies underlying many successful companies including Google’s PageRank search algorithm, E-Ink’s electronic paper, RSA’s cryptography algorithm, and Genentech’s recombinant growth hormone were discovered by scientists at universities who then commercialized via startups. Consider Amnon Shashua, professor of computer science at Hebrew University, who published many articles applying computer vision to traffic safety, including “Forward Collision Warning with a Single Camera.” Shashua might have left his work in the public domain for others to possibly exploit but instead self-commercialized his research by cofounding Mobileye, which supplies the driver-assistance systems in many vehicles and became Israel’s largest startup acquisition when sold to Intel for \$15.3B in 2017.

With universities increasingly concerned with economic development alongside their longstanding teaching and research missions, scholars have sought to better understand the factors that explain academic entrepreneurship. Rothaermel et al. (2007) and Markman et al. (2008) catalog 175+ such papers. Commercialization can take several forms including technology

licensing to established firms—and we do not claim that a startup is always the optimal vehicle for commercialization—but the literature has highlighted several reasons to understand new venture formation from academia. First, technologies developed in university labs are typically more embryonic than their industrial laboratory counterparts (Jensen and Thursby 2001). As a result, absent new venture development, these discoveries may go uncommercialized (Hsu and Bernstein 1997). Second, commercializing discoveries via venture formation addresses the changing nature of careers in academic science. Science, technology, engineering, and math doctoral degree awardees in the United States have long exceeded the number of available academic jobs (Cyranoski et al. 2011), whereas there has been a steady increase in university spinoffs. Because graduate students are instrumental in academic entrepreneurship (Hayter et al. 2017), there are scientific labor market implications of commercializing science. Finally, from an economic development standpoint, startups are disproportionately involved in job growth (Haltiwanger et al. 2013), and academic ventures tend to locate near prominent research scientists (Zucker et al. 1998), so regional growth may be spurred by venture formation.

Work on commercializing academic research via (discovering scientist-involved) startup formation has focused on two sets of antecedents. A first view, which we call the *resource munificence* perspective, claims that entrepreneurial opportunities proceed to commercialization based on resources available, often within a given geography. Resources could include financial capital (Samila and Sorenson 2011) and know-how, spanning technical and commercial domains, and may take place at various levels of analysis including groups (e.g., workshops) and even institutions (e.g., university collaborative relations with private enterprises). Financial capital for developing entrepreneurial opportunities such as from venture capitalists (VCs) is thought to be particularly sensitive to geographic colocation. Resources flow based on researcher or institutional prestige, so this literature has also examined the role of status (Stuart et al. 1999).

A second perspective, which we term the *discovery team composition* view, highlights the configuration and social context of the team that discovers the scientific advance. This branch of literature suggests that scientific teams with exposure to peers who have experience in commercializing science can substantially increase the propensity of engaging in entrepreneurship because of awareness, demonstration effects, professional legitimization, and experience with commercialization (Stuart and Ding 2006). Team composition itself can also impact entrepreneurial opportunity recognition and commercialization outcomes such as through social networks and experience (Baron 2006).

The literature review by Rothaermel et al. (2007) summarizes these two categories (see their figure 7 on p. 761). These theories have only rarely been assessed in a single analysis and even when examined jointly have a fundamental empirical problem impairing the entire literature on the antecedents of academic entrepreneurship: unmeasured latent commercializability. By this we mean that each scientific discovery has a distinct level of commercial potential, which may be difficult to discern (and is perhaps unclear even to the scientists). Indeed, the literature on academic commercialization frequently characterizes academy-originated technologies as *embryonic* (Jensen and Thursby 2001), which compounds the difficulty of ascertaining eventual suitability to the commercial market.

Researchers have only rarely attempted to control for latent commercializability. One example is found in Azoulay et al. (2007), who construct such a measure for the life sciences based on keywords assigned by PubMed that overlap with words in patent applications. However, even within a set of keywords, there may be vast differences in commercial potential. We instead tackle this confound by building on the method of Bikard and Marx (2019) of analyzing “twin” scientific discoveries that arguably have identical

commercial potential. We dramatically scale up their effort to include all fields of science over a 60-year period, studying the antecedents of startup commercialization among more than 20,000 twin discoveries. This approach allows us to examine the resource munificence and discovery team composition views on a comparative basis and while taking off the table technology differences (and their latent commercializability). Our twin-discovery approach therefore mitigates two inference problems plaguing the prior literature. First is the issue of spurious correlations resulting from unaccounted for differences in commercial potential. Second, even if estimated correlations are not spurious, without controlling for commercial potential, it is difficult to discern the degree to which results are because of selection.¹

Our study illustrates how not accounting for latent commercializability can dramatically alter inferences regarding the antecedents of academic entrepreneurship. We begin with a cross-sectional analysis on a matched sample drawn from the population of published academic findings (more than 42 million academic articles in the Web of Science (WoS), 1955–2017) but *without* controlling for latent commercializability. Through this analysis, we largely replicate prior results confirming the importance of both resource munificence and discovery team composition for entrepreneurial commercialization. When we account for commercial potential by analyzing twin discoveries, however, we confirm the discovery team composition view, but find limited evidence for the resource munificence perspective. Our empirical approach ensures that these differences are not caused by different variable definitions or data sources.

Moreover, controlling for latent commercialization refines our understanding of the role of discovery team composition. Only when examining twin discoveries can we conclude that prior results regarding peer effects in academic entrepreneurship are not driven by selection, for example, mentors pushing their students to choose projects with commercial promise. Namely, *even when considering the same scientific discovery*, scientists with entrepreneurial peers are more likely to commercialize that discovery via a startup. By the same token, although in the cross section we do not find an association between interdisciplinary research teams and entrepreneurial commercialization, once we account for latent commercializability, we find a robust positive effect. That is, when more interdisciplinary teams of scientists develop the same scientific discovery as less diverse teams, they are more likely to commercialize via startup formation.

We describe latent commercialization-based bias in the technology entrepreneurship literature in Section 2, followed by describing our empirical approach in Section 3. In Section 4, we compare results with and without controlling for latent commercialization.

In Section 5, we discuss how these results compare with the existing literature, and a concluding Section 6 reviews our contributions and highlights limitations.

2. Bias in the Literature Stemming from Latent Commercializability

In this section, we discuss the classic econometric issue of omitted variable bias (OVB) stemming from unmeasured and/or unobserved latent commercializability of a scientific advance in predicting entrepreneurial commercialization in ordinary least squares (OLS) regression. Consider a true regression model of an outcome of interest, $ENTCOMM_i$, which indicates whether the focal scientific advance i was commercialized via a startup. $RESOURCE_MUNIFICENCE_i$ captures variables proxying commercialization resources potentially available to the authors of the advance, such as the local abundance of potential funding from professional investors venture capitalists. $DISCOVERY_TEAM_COMPOSITION_i$ measures attributes of the scientific team such as commercial experience. The shadow commercial potential of the advance is captured by $LATENT_COMMERCIALIZABILITY_i$, and ϵ_i is the error term.

$$\begin{aligned} ENTCOMM_i &= \alpha_0 + \alpha_1 RESOURCE_MUNIFICENCE_i \\ &\quad + \alpha_2 DISCOVERY_TEAM_COMPOSITION_i \\ &\quad + \alpha_3 LATENT_COMMERCIALIZABILITY_i + \epsilon_i \end{aligned} \quad (1)$$

Now consider that $LATENT_COMMERCIALIZABILITY_i$ is unmeasured and thus omitted from the specification. Therefore, an OLS regression estimates the following equation:

$$\begin{aligned} ENTCOMM_i &= \alpha_0 + \alpha_1 RESOURCE_MUNIFICENCE_i \\ &\quad + \alpha_2 DISCOVERY_TEAM_COMPOSITION_i + v_i. \end{aligned} \quad (2)$$

Latent commercializability is omitted from the estimated regression and is instead captured within the error term v_i . Furthermore, there is good reason to believe that latent commercializability is positively related to the outcome variable. To fulfill the conditions of the Gauss-Markov theorem that OLS is the best linear unbiased estimator, the expected value of v_i , conditional on resource munificence and discovery team composition, must equal zero. However, there may be reason to believe that the covariance between latent commercializability and resource munificence (for example) may not be zero.

For example, if a given geographic locale contains many promising researchers and universities with

higher potential of producing a commercially successful product or service, that region may be more munificent with regard to venture capital funds. Similarly, discovery teams with commercially experienced members may select projects with more commercial potential, which will induce a positive correlation with the omitted variable, latent commercializability. Because the expected value of v_i , conditional on resource munificence and discovery team composition is not zero and because the omitted variable is related to the outcome variable, estimates of α_1 and α_2 are biased (the direction of bias compared with the true α_1 and α_2 depends on the sign on the various covariance relationships).

One remedy is to find a suitable proxy for latent commercializability to include in the regression. Azoulay et al. (2007) did so by constructing a measure of “latent patentability” of a faculty member’s research (and therefore patenting propensity by academic scientists). They write (p. 600): “While latent patentability typically has been assumed to be unobservable, we are able to devise a patentability score for each scientist in our sample by using keywords in the publications of scientists that have already applied for patent rights as a benchmark for patentable research, and then comparing the research of each scientist in our dataset to this benchmark. Although there is noise in this proxy, it nevertheless quite strongly predicts a patenting event.” Controlling for latent commercializability—which is rare in the technology management and entrepreneurship literature—would help address OVB but may introduce other potential biases related to measurement error, precisely because of the noisy measurement.

Our goal is to address latent commercializability-based OVB via a different empirical strategy, one that both directly controls for the technical advance itself and provides natural comparison groups. We examine instances of scientific codiscovery in which there is variation in both the outcome and explanatory variables of the regression model, and by including twin discovery fixed effects (more details in the next section), we aim to sidestep bias stemming from both omitted variables and measurement error.² To foreshadow our results, we find that addressing omitted latent commercializability in this way changes inference on the importance of various explanatory variables relative to the prior literature.³

3. Empirical Approach

As noted earlier, the latent commercializability of scientific discoveries is a critical confound in the literature on academic entrepreneurship. The ideal experiment would involve random matching of researchers and discoveries, which is impractical as few scholars would consent to being assigned

projects or colleagues. Instead, we take advantage of the fact that different research teams sometimes make duplicate (or very similar) discoveries. We label these discoveries twins because they allow us to hold constant technological differences in shaping startup commercialization. The counterfactual is therefore as follows: if a given scientific advance had been made in two different entrepreneurial ecosystems, is there a tendency for the advance made in the more munificent financial environment to become commercialized by a startup? In this section, we outline the method for assembling the twins data set.

We adopt and expand on a method of identifying twins based on common citation patterns (Bikard and Marx 2019). Citations act as a window into the allocation of credit within the scientific community (Cozzens 1989), so one can infer codiscovery status from papers with distinct authorship but similar citation patterns. Although codiscoveries are uncommon in the social sciences, they are frequent in the hard sciences as many research teams are chasing the same scientific frontier. Journal editors may appreciate the opportunity to publish concurrent scientific advances—indeed, twins often appear back-to-back in the same issue of the same journal—as a reaffirmation of the accuracy of the finding. Indeed, Bikard and Marx (2019) verified the method by hiring 10 postdoctoral researchers to manually review dozens of twins that had been identified automatically, with no false positives reported.

We begin by replicating exactly the methodology of Bikard and Marx (2019), finding all pairs of papers that satisfy five conditions: (1) published no more than a year apart; (2) zero overlap between the authors; (3) are cited at least five times; (4) share 50% of forward citations; and (5) jointly cited by at least one other paper (i.e. in the same reference list). Our methodology departs from theirs in that, instead of limiting our analysis to articles from the top 15 scientific journals between 2000 and 2010, we apply these criteria to the entire WoS from 1955 to 2017. Doing so yields a set of potential twin discoveries embodied in 40,392 papers. The next step in the methodology is to determine which of the potential twin discoveries are cited not just jointly (i.e., in the same reference list) but adjacently (i.e., within the same parentheses). Adjacent citations suggest that forward-citing researchers are unable to attribute the discovery to a single paper, with the references listed within the citation parenthesis receiving coattribution.

Identifying adjacent citations involves inspecting the text of papers that jointly cite what may be twin discoveries. For the 40,392 potential twin papers, both appear in the reference lists of more than 1.2M papers. Retrieving all such papers is impractical, as many if not most published articles reside behind paywalls

and are inaccessible at scale. However, PDFs of many papers are freely available—sometimes in draft form—and have been indexed by Google Scholar (GS). Although GS does not support bulk downloads, over a period of 19 months, we were able to retrieve approximately 280,000 publicly available, nonpaywalled PDFs of the 1.2M papers that jointly cited our potential twin discoveries. For 29,257 of the 40,392 potential twin discoveries, we were able to determine whether they were adjacently cited by the PDFs that cited both of them. Of those, we found that 23,851 potential twin papers were indeed cited adjacently.⁴ These comprise our population of twin discoveries, which should have similar latent commercial potential.⁵ These twin papers reported results from 11,923 twin discoveries. Appendix A provides more detail on the twin discoveries, which hail from more than 3,000 academic institutions in 106 countries and span more than 200 scientific fields.

3.1. Dependent Variable: Entrepreneurial Commercialization of Scientific Discoveries

Our dependent variable indicates whether academic researchers commercialize their discoveries via a startup. To our knowledge, a large sample of academic scientific discoveries commercialized via startups has not been previously assembled. Several studies of technology transfer have tracked out-licensing or other forms of commercialization more generally, not necessarily via new venture formation (see Rothaermel et al. 2007 for a review). There have also been academic institution-specific studies of new venture formation (Kenney and Goe 2004, O'Shea et al. 2005), as well as sector-specific studies of commercial science, most notably in the biotechnology industry (Zucker et al. 1998, Stuart and Ding 2006). Our aim, however, is to identify entrepreneurial commercialization of scientific discoveries at scale, spanning academic institutions, industrial sectors, and geography. Aside from the benefit of algorithmically assembling a large empirical sample, our method allows us to directly trace new ventures all the way back to a particular scientific advance, a feature also novel to the literature.

We measure entrepreneurial commercialization in two ways. (1) Via patent-paper pairs (PPPs) (Murray 2002) where the patent is assigned to an entrepreneurial venture. The premise is that while scientific publications are the currency of academia, patents and their associated legal protection are valued much more in the commercial domain. Our effort is aimed at identifying patents granted to entrepreneurial ventures that cover the same or similar scientific advance in which there is overlap between inventors and authors. We start by finding the subset of academic discoveries that are cited by patents (Marx and Fuegi 2020) and check for overlap between the authors of

the paper and the inventors named on the patent. Article authors and patent inventors are compared individually, with an overall match score computed according to (a) whether the surname is an exact versus fuzzy match; (b) frequency of the surname in the WoS and the patent corpus; and (c) whether the middle initial matches (more details are provided in Appendix B). A weighted average of author/inventor overlap is computed to yield an overall article/patent match score.⁶ However, not every patent-paper pair represents entrepreneurial commercialization. For example, one or more scientists on a paper may cooperate with an established firm to commercialize the discovery. We thus subset the list of PPPs to those assigned to startups, as determined from VentureSource and Crunchbase.

Our second method involves U.S. Small Business Innovation Research (SBIR) grants. The SBIR program is targeted at encouraging “domestic small businesses to engage in federal research and research & development that has the potential for commercialization” and has awarded nondilutive funding in excess of \$45B since the program was initiated in 1982 (www.sbir.gov/about). We interpret pursuing SBIR funds as an indicator of commercialization aspirations. The SBIR channel of identifying commercialization attempts does not rely on observed patenting: this may be an important complement to the PPP measure, as Fini et al. (2010) suggest that only about a third of businesses started by academics are based on patented inventions. Moreover, the literature’s reliance on patent data are likely related to the fact that our understanding of technology commercialization heavily relies on the biotechnology industry (Hsu 2008), as patents are well understood to be important as an appropriation method in that industry (Levin et al. 1987). As with patent-paper pairs, we calculate the pairwise overlap between scientists on a focal article and either the primary contact or principal investigator of SBIR awards up until five years after the publication of the article. If multiple SBIR awards have identical author-overlap scores, we break ties with temporal proximity.

Overall, we find 139 academic articles that were commercialized via PPPs assigned to startups and 89 that were commercialized via SBIR awards, for a total of 228 entrepreneurial commercialization events. Appendix B also provides validation of the measure, confirming via web research a stratified random sample that both PPPs and overlapping SBIR grants truly reflect instances of a startup commercializing an academic discovery with the involvement of one of the original scientists. In short, we verified 20 of 20 of the PPP-based commercialization events and 19 of 20 SBIR-based events.

3.2. Explanatory Variables

Our explanatory variables fall into the aforementioned categories of resource munificence and discovery team composition. Resource munificence is often tied to geography (Samila and Sorenson 2011), so we constructed a lagged count of venture capital investments in the same postal code as the focal article. Resources also often accrue to high-status actors, so our second and third measures of munificence reflect the prestige of the discovery team and their associated institutions (Stuart et al. 1999). Each of these variables is calculated as a count of publications (per author, or per institution) in the same scientific field as the focal paper. WoS assigns each article to 1 of 251 scientific fields.⁷

Regarding discovery team composition, a first variable measures the interdisciplinarity of the scientists. This is calculated as one minus the Herfindahl-Hirsch index of scientific fields for articles written by the authors. If all scientists on the focal article published all of their papers in the same scientific field, this variable is zero. A second explanatory variable measures whether the previous collaborators of authors on the paper include a star commercializer. This variable is reminiscent of the measure of Stuart and Ding (2006) of the number of prior collaborators who served as founders or advisory board members of startups that filed for an initial public offering (IPO), but our measure differs in three ways. First, we measure involvement with early-stage ventures, not just those that complete an IPO. Second, instead of summing all instances of entrepreneurial involvement, we focus on star serial entrepreneurs (above the 75th percentile of entrepreneurially commercializing academic scientists in the year of the scientist’s most recent collaboration; similar results are obtained at the 50th or 90th percentile). Third, we check whether any scientist on the discovery team had previously collaborated with a star. Additional characteristics of star commercializers are available in Appendix C. As a third team composition covariate, we control for whether any of the authors on the paper is herself a star commercializer.

3.3. Empirical Specification

Following epidemiological twin studies (Carlin et al. 2005), we estimate the likelihood of commercialization using fixed effects for articles reporting a twin discovery. The regression equation is

$$\begin{aligned} ENTCOMM_{ij} &= \alpha_0 + \alpha_1 RESOURCE_MUNIFICENCE_{ij} \\ &\quad + \alpha_2 DISCOVERY_TEAM_COMPOSITION_{ij} \\ &\quad + \alpha_3 X_i + \gamma_j + \epsilon_{ij}. \end{aligned} \quad (3)$$

In the specification, j represents the twin discovery and i represents an article reporting the twin discovery. The term $ENTCOMM_{ij}$ captures whether the focal article was commercialized by a startup. Variables related to local venture capital investments and the prestige of the institution and discovery team are captured in $RESOURCE_MUNIFICENCE_{ij}$. The $DISCOVERY_TEAM_COMPOSITION_{ij}$ variables measure the interdisciplinarity of the scientific team and whether the scientists on a given article had previously collaborated with a star entrepreneurial commercializer. The term X_i represents controls for the number of authors and count of citations from industry patents, γ_j is a fixed effect for the twin discovery, and ϵ_{ij} is the error term. We estimate this equation using linear probability models with robust standard errors. Following Beck (2018), in the robustness checks of Table 5, we also estimate conditional logit models, which exclude any twin discovery where neither is commercialized, with similar results.

4. Results

We present results in two steps. Before proceeding to analyze the entrepreneurial commercialization of academic science via our twins methodology, we present cross-sectional estimates drawing from the 42M+ scientific publications contained in the WoS. Several findings from the past literature can be replicated in this setup, which does not account for latent commercializability. Then we contrast the cross-sectional results with those obtained via the twin-paper setup described previously. Our motivation for doing this is twofold. First, as noted previously despite hundreds of papers on related topics, resource

munificence and discovery team composition factors have only rarely been jointly considered. Second and more importantly, to the extent that our findings using the twins methodology differ from prior work, one might suspect that this is because of variable construction or the scope of the data analyzed. As noted previously, past work has frequently analyzed patented inventions, invention disclosures, or projects from a small number of universities. We are largely able to replicate prior results using a sample drawn from the universe of scientific publications. However, when addressing technology and latent commercializability differences via the twins method, the magnitude and sometimes the sign of results change materially.

4.1. Cross-Sectional Results

The WoS contains more than 42 million academic articles. Among these are 11,340 instances of entrepreneurial commercialization. Of those, 8,361 were found via patent-paper pairs and 2,966 via SBIR grants.⁸ One approach would be to conduct a cross-sectional analysis of the entire WoS, but differences between such results and those obtained using the twins methodologies might be ascribed to differences in the samples. Indeed, descriptive statistics segmented by twin versus nontwin observations (panel A of Table 1) reveal substantial differences between the twins subsample and the larger population. The distribution of our measures of both resource munificence (*author prestige*, *institution prestige*, and *natural-log transformed VC investments in the postal code*) and discovery team composition (*interdisciplinarity* and *prior work w/star commercializer*) significantly differ

Table 1. Difference-of-Means Tests for Twin vs. Nontwin Papers

	Average for twins	Average for nontwins	$p <$
Panel A: All twins (23,851) vs. all nontwins (42,051,322)			
Author prestige	2.963	1.678	0.00
Institution prestige	6.740	4.899	0.00
Ln same-postalcode investments (CB)	0.752	0.400	0.00
Interdisciplinarity	0.448	0.479	0.00
Prior work w/star commercializer	0.032	0.004	0.00
Panel B: Matched twins (19,233) vs. matching nontwins (18,628)			
Author prestige	2.966	2.966	0.94
Institution prestige	6.744	6.791	0.01
Ln same-postalcode investments (CB)	0.752	0.752	0.94
Interdisciplinarity	0.448	0.461	0.00
Prior work w/star commercializer	0.032	0.031	0.71

Notes. Table reports difference-of-means tests for twin papers and nontwin papers. Panel A compares twin papers versus all academic papers from the WoS. Panel B compares the subset of twins and WoS papers that can be matched using 1:1 coarsened exact matching. Matching variables include author prestige, institution prestige, same-postalcode investments, and whether the authors had prior affiliation with a star commercializer. Nonbinary variables were segmented into 10 bins each. For computational efficiency, matching was performed on a 10% sample of all WoS papers.

between the two subsamples. In particular, the average value for the twins subsample is higher than that of the nontwins for four of these five variables (all except *interdisciplinarity*).

This imbalance suggests that the data generation process for twins is different than that of the rest of the WoS; perhaps twin discoveries are more important than the average scientific publication. Therefore, we preprocess the WoS data using coarsened exact matching to balance covariates with the twins sample: *author prestige*, *institution prestige*, natural-log transformed *VC investments in the postal code*, *interdisciplinarity*, and whether the authors had prior affiliation with a star commercializer (*prior work w/star commercializer*). Continuous variables were segmented into 10 bins each for purposes of matching. As a result, each observation was categorized into 1 of 559 strata (i.e., combinations of bins for purposes of matching with the relevant variable from the twin subsample). For strata where both twin and nontwin observations were categorized, one nontwin observation was selected (randomly) for each twin in the strata. Of the 23,851 twins, 19,233 were matched to a nontwin.⁹

The resulting sample balance is shown in panel B of Table 1. All of the variables are now much better balanced in value. In essence, the matching procedure trades off a (much) larger sample size to match the twin sample on key observables.

We use the resulting matched sample to conduct a cross-sectional regression analysis in Table 2. These

regressions do *not* control for latent commercializability and therefore are susceptible to the omitted variable bias previously discussed. All specifications include controls for number of paper authors, and counts of citations from industry patents, and fixed effects for year, country, and scientific field. The estimating equation for Table 2 is therefore

$$\begin{aligned} \text{ENTCOMM}_{ij} &= \alpha_0 + \alpha_1 \text{RESOURCE_MUNIFICENCE}_{ij} \\ &+ \alpha_2 \text{DISCOVERY_TEAM_COMPOSITION}_{ij} \\ &+ \alpha_3 X_i + \eta_i + \zeta_i + \theta_i + \epsilon_{ij}, \end{aligned} \quad (4)$$

where η_i is a fixed effect for year of the article, ζ_i is a fixed effect for the country of the article's corresponding author, and θ_i is a fixed effect for the scientific field of the article as assigned by WoS.

Columns 1–6 of Table 2 follow the literature by examining each explanatory variable independently. We find positive, statistically significant effects at the $p < 0.01$ level for two measures of resource munificence: *author prestige* and *VC investments in the postal code*, as well as for two measures of discovery team composition (*prior work w/star commercializer* and *star commercializer on paper*). These results are consistent with that of prior work. When all covariates are considered jointly in column 7, we find similar effects as the individual regression, with the exception of the *author prestige* variable, which is less precisely estimated.¹⁰

The results suggest, consistent with prior research, that local financial capital facilitates commercialization,

Table 2. Cross-Sectional Estimates for Startup Commercialization of Academic Science

Notes. Sample is as described in panel B of Table 1, including both the twin discoveries and articles from the full WoS that could be matched closely on observables as shown in panel B of Table 1. Mean of the dependent variable = 0.003. All models are estimated with OLS with fixed effects for year, country, and WoS subject, as well as robust standard errors. Not shown are controls for number of authors and the count of citations from patents to the scientific articles.

* $p < 0.1$; ** $p < 0.05$; *** $p < 0.01$.

supporting the resource munificence view. Moving to discovery-team composition factors, we likewise confirm the findings of Stuart and Ding (2006) regarding the strong role of both having a star commercializer either on the discovery team or among one of the team's prior collaborators. By replicating prior results from the literature based on a matched sample drawn from the full population of academic articles since the 1950s, we hope to alleviate concerns that the differences we find in the following section via our twin-discovery method are because of either data or variable construction differences. Next, we show that the results differ when controlling for latent commercialization.

4.2. Twin-Discovery Results

The previous analysis embeds latent commercializability effects in the error term, yielding OVB because of the theoretical correlation between latent commercializability and entrepreneurial commercialization and the correlation between latent commercializability and both groups of independent variables of interest. Our approach to overcoming OVB is to constrain our sample to just the scientific twins, including twin fixed effects in each specification. We begin in Table 3 by emulating the specification structure from Table 2, limiting the sample to articles that report twin discoveries, and replacing fixed

effects for year, country, and scientific field with fixed effects for the twin discovery as in Equation (3).

In columns 1–3, we reassess the role of resource munificence using the twins analytic strategy. Compared with column 1 of the cross sectional regression in Table 2, when accounting for latent commercializability in column 1 of Table 3, *author prestige* does not materially impact entrepreneurial commercialization. Similar to the cross-sectional result, *institution prestige* remains insignificant. In addition, we find that the entrepreneurial commercialization of academic science is not explained by the number of local VC investments when accounting for latent commercializability (compare column 3 of Table 3 versus Table 2). Although we discuss in more detail how our results relate to findings from the literature in Section 5, one explanation for the difference in the local VC effect may be selection of researchers with higher commercial potential projects into particular geographic regions.

In columns 4–6 of Table 3, we apply the twin-discovery methodology to assess how controlling for latent commercializability impacts the discovery team composition effects (relative to the cross-sectional estimates). When interpreting these measures, we remind the reader that our variables do not necessarily reflect the composition of the founders of the startup but rather the team of scientists that

Table 3. Twin-Discovery Estimates for Startup Commercialization of Academic Science

Twin-discovery fixed effects	Yes	Yes	Yes	Yes	Yes	Yes	Yes

Notes. Observations are articles reporting twin academic discoveries, generated as per the procedure described in Section 3. Mean of the dependent variable = 0.009. All models are estimated with OLS using fixed effects for the twin scientific discovery and robust standard errors. Not shown are controls for number of authors, the count of citations from patents to the scientific articles, and whether the article was a twin in multiple discoveries.

* $p < 0.1$; ** $p < 0.05$; *** $p < 0.01$.

pioneered the original scientific finding. Under our definition, one or more of the authors were indeed involved with the startup. Column 4 indicates that discoveries where the scientific team is more interdisciplinary are somewhat more likely ($p < 0.10$) to be commercialized by startups than when the discovery team is homogeneous with respect to scientific field. Column 5 shows that discoveries are more likely to be commercialized via startups when one of the authors is a star commercializer. In column 6, we find similar confirmation for discovery teams where one of the authors previously worked with a star commercializer. All resource munificence and discovery team composition covariates are included in column 7, which strengthens statistical significance on the estimated coefficient for interdisciplinarity to the $p < 0.05$ level.¹¹

Using estimated coefficients from column 7, a one standard deviation increase in interdisciplinarity (0.27) corresponds to a 2.7% increase in the likelihood of commercialization by a startup. The presence of a star commercializer among the scientists' past collaborators is associated with a 4.1 percentage point increase in commercialization and having a star commercializer among the authors themselves predicts a 9.5 percentage point rise in the likelihood of commercialization. Thus, we obtain quite different results when controlling for latent commercializability via our twin-paper strategy.

4.3. A Deeper Dive into Discovery Team Composition Effects

A key difference between the cross-sectional and twin regressions is the emergence of a role for interdisciplinarity in the commercialization of academic science. In Table 4, we dig deeper into the nature of interdisciplinarity and stars. Interdisciplinarity may take a number of forms. An interdisciplinary team could be composed of several specialists from different scientific fields, possibly with one boundary spanner. Alternatively, an interdisciplinary team might be composed of generalists who are themselves interdisciplinary. In columns 1–5 of Table 4, we explore which forms of interdisciplinarity matter for entrepreneurial commercialization. In column 2, we replace the *interdisciplinarity* variable from Table 3 (shown in column 1 for comparison) with an indicator for above-mean interdisciplinarity. The coefficient remains positive, although weaker. In column 3, we count the number of unique primary scientific fields among the authors on the paper. By “primary,” we mean the scientific discipline in which each author publishes most often. The positive, statistically significant estimate of the associated coefficient suggests that having scientists from a variety of scientific fields is important and not just having a set of scientists from the same discipline who also work relatively

often in other areas. The magnitude of the estimated coefficient on the simple count of scientific fields represented is smaller than the more subtle measure of interdisciplinarity among all authors, however. This suggests that merely having more scientific fields represented does not fully explain the findings in column 1.

Although column 3 suggests that specialization is useful, column 4 clarifies that the optimal discovery team for commercialization requires more than a team of specialists. The covariate in this column counts the number of scientists who fully specialize (i.e., all of their work is published in a single scientific field). If specialization alone were critical to the commercialization process, we might expect this coefficient to be significant, but it does not appear so. Alternatively, perhaps it is the case that an ideal configuration would combine a set of specialists with a boundary spanner. In column 5, we calculate each scientist's individual level of interdisciplinarity and then enter as a covariate the difference between the most interdisciplinary scientist and the mean of the team. The negative coefficient suggests that having one scientist with much more interdisciplinarity than most does not facilitate commercialization. Taken together, columns 2–5 suggest that a well-rounded team of well-rounded scientists may be particularly effective in spurring entrepreneurial commercialization. As we discuss further in Section 5.3, this result is consistent with the claim of Baron (2006) that “opportunity recognition can be enhanced by providing potential entrepreneurs with a very broad range of experience. . . the broader this experience. . . the more likely the entrepreneurs will be to perceive connections between seemingly unrelated events or trends” (p. 117).

We similarly explore whether alternative definitions of *star commercializer* and *prior work w/star commercializer* overturn the positive estimated effects from Table 3. In columns 6 and 7 of Table 4, we see that replacing those measures with indicators for above median values (column 6) or being in the top 10% of each distribution (column 7) also results in positive and statistically significant estimated coefficients.

The remaining column 8 of Table 4 verifies that it is the presence of a star *commercializer* among the scientists' past collaborators that explains the patterns in Table 3 and not simply an association with a prominent researcher. We replace the star commercializer variable with an indicator for a star scientist—those whose citation count per article (in a five-year window following publication) was in the 99th percentile—among one's past collaborators. Following Zucker et al. (1998), we would expect this coefficient to be statistically significant, but it is imprecisely estimated here. We conclude that star commercializers, as opposed to star scientists,

Twin-discovery fixed effects	Yes	Yes	Yes	Yes	Yes	Yes	Yes	Yes

Notes. Observations are articles reporting twin academic discoveries, generated as per the procedure described in Section 3. Column 1 repeats column 7 of Table 3. All models estimated with OLS, with robust standard errors. Mean of the dependent variable = 0.009. Each model includes fixed effects for the twin discovery. Not shown are controls for number of authors, the count of citations from patents to the scientific articles, and whether the article was a twin in multiple discoveries.

* $p < 0.1$; ** $p < 0.05$; *** $p < 0.01$.

facilitate the entrepreneurial commercialization of science.

4.4. Robustness and Placebo Tests

Finally, we establish the robustness of the findings thus far to a variety of specifications. Column 1 of Table 5 repeats column 7 of Table 3 for comparison. Column 2 re-estimates column 1 using conditional logit (Beck 2018). Because the maximum likelihood estimator drops groups without variation in the dependent variable, the fixed effects for each twin discovery reduces the number of observations. Statistical significance is reduced somewhat for the interdisciplinary result ($p < 0.08$) but otherwise resembles column 7 of Table 3. In column 3, we present the OLS

specification analog to the logistic regression from column 2 by manually limiting observations to the set of twin discoveries with variation in the outcome variable. When doing so, OLS results closely resemble logit.

As noted previously, we were able to check for adjacent citations (future citations that reference our candidate twin papers within the same parentheses) in only 280,000 of the 1.2 million papers that jointly cited potential twins. Although for 38% of our twins we found only a single adjacent citation, that figure may be understated as we could not inspect three-fourths of the cociting PDFs. We thus check that our results are robust among twins that we *can* confirm were adjacently cited multiple times. Column 4

confirms the results are similar, with a slightly smaller t statistic for the interdisciplinarity coefficient.

Finally, in column 5 of Table 5, we perform a placebo test by randomly generating values for the dependent variable. Doing so yields no statistical significance on any covariates. In unreported results, this placebo test also fails if the distribution of the randomly generated dependent variable matches that of the actual dependent variable (i.e., much less than 1% of papers are commercialized by startups).

Next, we check that the null results regarding the effects of resource munificence factors are not driven by our particular variable construction. To this end, we generate specification maps (King et al. 2019). In Figure 1, we graph the estimated *author prestige* coefficient using the specification from column 7 of Table 3, but substituting various alternative ways of measuring the construct: logged and unlogged count of papers, a count of citations instead of papers, average journal impact factor (JIF) for authors on the paper, and average eigenfactor (a measure of the importance of journals that cite the author's papers). All estimated coefficients are not different than zero

(statistically). Figure 2 follows a similar logic in exploring whether the estimated zero effect of *institutional prestige* depends on its exact measurement, finding no statistically significant effects using any alternative measure.

In Figure 3, we investigate whether the noneffect of local venture capital availability is an artifact of the measure of the construct. We plot the estimated coefficient (and 95% confidence interval) based on the specification of column 7 of Table 3, but measuring VC investment in alternative ways: logged investments in the postal code; unlogged investments; replacing the count of investments per postal code with a count of liquidity events (i.e., IPOs or acquisitions); replacing the data source of investment counts using VenturExpert instead of Crunchbase; and measuring local VC investment at the core-based statistical area (CBSA) level instead of the postal code. All of these measures also result in an estimated VC effect not statistically different from zero.

In Figure 4, we create another specification map (King et al. 2019) that plots the regression coefficient of *Ln same-postalcode investments (CB)* using various

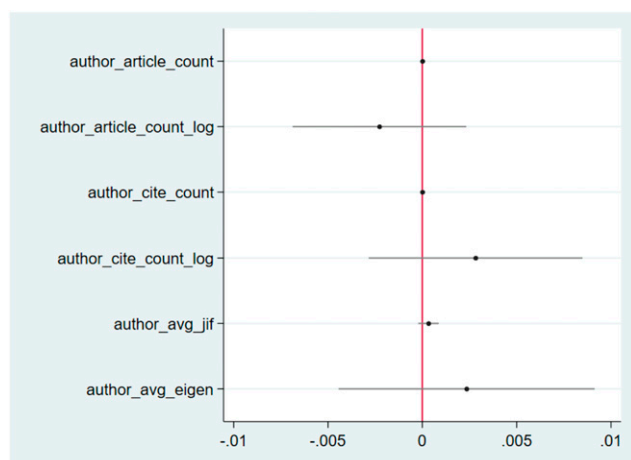

Table 5. Robustness and Placebo Tests for Startup Commercialization of Twin Discoveries

	Dependent variable and sample

Estimation	OLS	Logit	OLS	OLS	OLS
Twin-discovery fixed effects	Yes	Yes	Yes	Yes	Yes

Notes. Observations are articles reporting twin academic discoveries, generated as per the procedure described in Section 3. Column 1 repeats column 7 of Table 3. Column 2 re-estimates column 1 using logistic regression, which drops twin discoveries whether neither article is commercialized. Column 3 re-estimates column 2 using OLS but for the same sample (i.e., where one of the twin articles was commercialized). Column 4 re-estimates column 1 for the subset of twins found to have been cited adjacently by multiple papers. For column 5, we generate random values for the dependent variable as a placebo test. Robust standard errors. Each model includes fixed effects for the twin discovery. Not shown are controls for number of authors, the count of citations from patents to the scientific articles, and whether the article was a twin in multiple discoveries.

* $p < 0.1$; ** $p < 0.05$; *** $p < 0.01$.

Figure 1. (Color online) Specification Map for Author Prestige

Notes. Coefficient estimates and confidence intervals are based on the final column of Table 3, (author_article_count). Perturbations of author prestige include logged (_log) and unlogged count of papers, a count of citations (_cite_) instead of articles, average JIF for authors on the paper (_jif), and average eigenfactor (_eigen) for authors on the paper. Confidence intervals appear tight for unlogged variables relative to logged variables.

specifications. The first row shows the estimated coefficient and 95% confidence interval from column 7 of Table 2, which is positive and statistically distinct from zero. In the second row, we replace the matched subset of the 42+M papers in WoS with the twin papers (i.e., the same sample as in Table 3), but *without* twin fixed effects. The estimated coefficient is still statistically distinct from zero, indicating that the null result in Table 3 is not simply because of the sampling population. The third row resembles the second row, except that the sample is reduced (at random) to only one paper from each twin discovery such that it is not possible to use fixed effects for the twin discovery. In this specification, with slightly less than half the data points, the coefficient is still positive and significant. Only in the fourth row, where we include twin fixed effects (column 7 of Table 3) and therefore account for latent commercializability, does the estimated coefficient on *Ln same-postalcode investments (CB)* become indistinct from zero.

In Appendix D, we examine whether the results from Table 3 are heterogeneous. In summary, we find that the role of stars and interdisciplinarity depends on geographic location, discipline, and time period.

5. Calibration with the Literature and Future Directions

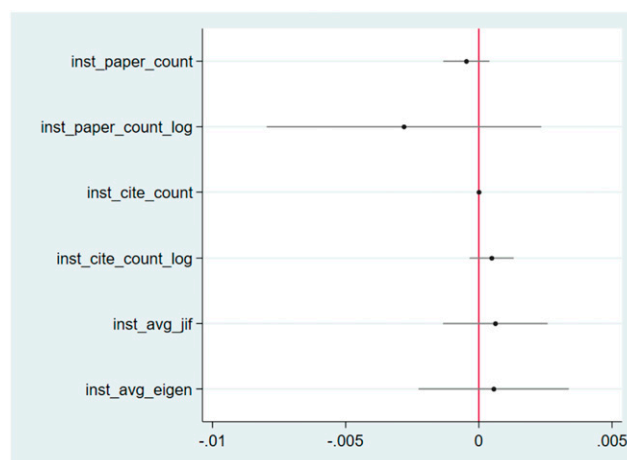

We now discuss how the population-level, cross-sectional estimates contrast with those from the twin study and how these results compare with those reported in the literature.

5.1. Entrepreneurial Ecosystem Resource Munificence

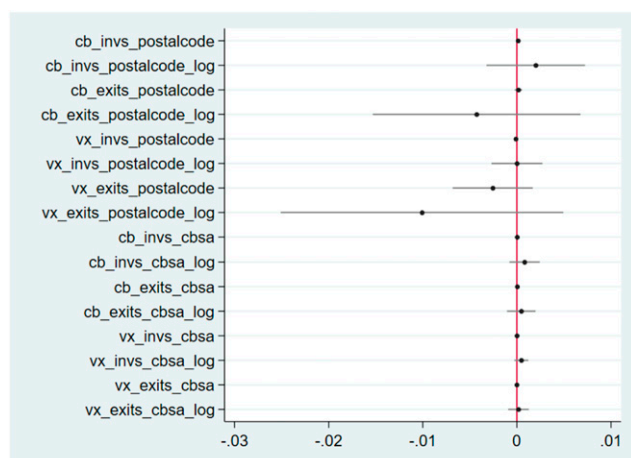

The munificence of resources required to commercialize entrepreneurial discoveries has been a frequent subject of inquiry. For example, Zucker et al. (1998) report that U.S. states with more academic scientists who have outsized academic output (stars) are home to more biotechnology startups, particularly in the nascent phase of industry development. Their study does not establish direct linkages between startups and academic scientists, but their findings have generally been interpreted to suggest that the localized knowledge of highly productive scientists may be important in the geography of entrepreneurial commercialization. Such an interpretation is consistent with what we see in the matched cross-sectional results in column 1 of Table 2. However, when accounting for latent commercialization via our twins methodology (in Table 3 and in the robustness results of Figure 1), we no longer find support for the role of prominent scientists.

Similarly, an extensive literature has found a connection between the local munificence of venture capital and the founding of new firms (Samila and Sorenson 2011). We see a similar association in the cross-sectional analysis of Table 2 but not when we use our empirical approach of controlling for latent commercializability in Table 3. The null results are confirmed in a variety of robustness tests using alternative measures for the local VC investment construct in Figure 3, as well as alternative empirical

Figure 2. (Color online) Specification Map for Institutional Prestige

Notes. Coefficient estimates and confidence intervals based on the final column of Table 3, (inst_paper_count). Perturbations of institution prestige include logged (_log) and unlogged count of papers, a count of citations (_cite_) instead of articles, average JIF for authors on the paper (_jif), and average eigenfactor for authors on the paper (_eigen). Confidence intervals appear tight for unlogged variables relative to logged variables.

Figure 3. (Color online) Specification Map for VC Investment

Notes. Coefficient estimates and confidence intervals based on the final column of Table 3. Perturbations of VC investment include logged (“_log”), unlogged, and replacing the count of investments per postal code (“_invs_”) with a count of liquidity events (i.e., IPOs or acquisitions, “_exits_”) per postal code. Additionally, the count of investments via CrunchBase (“cb_”) is replaced by that from VentureExpert (“vx_”), and we explore both counts within the postal code (“_postalcode_”) and Core-Based Statistical area (“_cbsa_”). Confidence intervals appear tight for unlogged variables relative to logged variables.

specifications in Figure 4. The fact that we fail to find any connection once applying the twins methodology raises the question of whether this effect extends to *academic* entrepreneurship. It could instead be that discoveries in close proximity to sources of capital simply have more commercial potential, raising the possibility that commercially minded academic scientists select into regions with locally available financial capital.

Note that both papers of Zucker et al. (1998) and Samila and Sorenson (2011) are set in the United States and (largely) in the time period before the year 2000. Although it is difficult to directly compare our twins results on commercializing science with these papers (the outcome variables and the samples differ), we do not find evidence for the local knowledge capital or VC effect in our analysis of sample heterogeneity (Appendix D). This suggests that further research on the role of resource munificence while taking into more careful account the nature of technical opportunities produced in the local geography, especially as related to academic entrepreneurship, may be warranted.

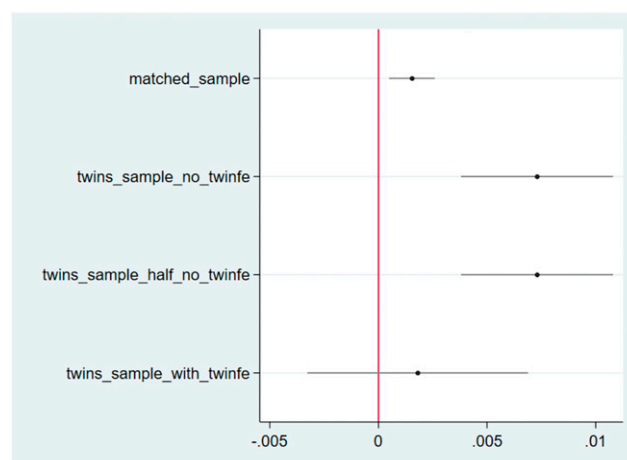

5.2. Discovery Team Composition: Star Commercializers

Whereas we failed to find support for resource munificence when accounting for latent commercialization, we affirm the role of star commercializers

(Stuart and Ding 2006) both in the matched cross-sectional analysis and when using the twins methodology. The positive effects are robust to a variety of alternative ways of measuring star commercializers (as seen in Table 4). In addition to reconfirming prior findings, by controlling for latent commercialization, we show that peer effects are not limited to project selection. That is, one might suspect that prior association with a star commercializer might lead a focal researcher to pick research projects with greater commercial potential. This may well be true, but our results show that *even given the same scientific discovery*, those with exposure to entrepreneurial peers are more likely to commercialize their research.

Our findings are consistent with broader work on peer effects, such as Nanda and Sørensen (2010), who use Danish data from 1980 to 1997 and find a positive immediate workplace peer effect on entrepreneurial entry. Although it is difficult to directly compare our results to these studies because of different samples (among other things), the operative mechanisms behind the positive peer effects are demonstration effects (“if I can be an entrepreneur, you can as well”) and information/resource effects (“in order to be credible to investors in this space, you have to have more than a product prototype”).

It is important to stress that our results should not be interpreted as causal evidence for peer effects in academic entrepreneurship. Although it is important to hold constant the nature of the discovery, we do not address the endogeneity of discovery team formation.

Figure 4. (Color online) VC Investment Appears to Predict Entrepreneurial Commercialization Until Twin Fixed Effects Are Applied

Notes. The first row, *matched_sample*, is based on column 8 of Table 2. The second row, *twins_sample_no_twinfe*, is based on the same sample as column 8 of Table 3 but does not include twin fixed effects. The third row, *twins_sample_half_no_twinfe*, resembles the second row but only includes one of the each pair of twin papers. The final row, *twins_sample_with_twinfe*, is based on the final column of Table 3, including twin fixed effects.

Perhaps the original scientist recruits a star commercializer to join the discovery team if a startup opportunity is sensed. We know who the corresponding author is on each paper but not the order in which the team was *assembled* (not just order of authorship) in order to rule out this possible alternative. What we can rule out by controlling for latent commercializability is that project selection was influenced by prior exposure—that is, pushing scientists toward projects that are more applied and thus have greater commercial promise.

Moreover, Lerner and Malmendier (2013), using randomized graduate business student section assignments between 1997 and 2004, find peer effects dampen entrepreneurial entry (but that those who enter are more successful, suggesting that peers may provide information allowing focal individuals to properly assess their prospects). Their negative peer effect seems to stem from a screening function that may serve as a check to would-be entrepreneurs who may not have realized the many obstacles to successful entrepreneurial entry. Although we do not study commercialization performance, our heterogeneity results (Appendix D) in comparison with this study suggests that perhaps industry conditions outside of the biotechnology and life sciences may curtail the role of (star commercializer) peer effects. Consistent with the study of Lerner and Malmendier (2013), we do not find a general peer effect outside of the biotechnology and life science contexts. There may be less of a compelling peer screening function outside of the specialized expertise in the life and health sciences.

Although the effects of peers on (academic) entrepreneurial starts is therefore not settled, especially because there are more than a few differences in the research contexts across the studies, we believe that a fruitful path forward is tying peer effects to the specific entrepreneurial opportunity. In contrast to the prior peer effects literature that treats such opportunities as unspecified and unmeasured, our study begins the process of specifying the (scientific) advance giving rise to a potential entrepreneurial opportunity. At the same time, it will be important to pay particular attention to possible differences in the peer effect process in the life and health sciences compared with other scientific sectors. Such an empirical strategy holds the promise of revealing more on how and why the nature of peer effect interaction matters for entrepreneurial commercialization.¹²

5.3. Discovery Team Composition: Interdisciplinarity

Finally, we consider the interdisciplinary nature of discovery teams. Interdisciplinarity has been frequently studied (Leahey et al. 2017), although rarely

in the context of entrepreneurship. The most relevant articles of which we are aware are Bercovitz and Feldman (2011) and Kotha et al. (2013), both of which examine the licensing of university invention disclosures as opposed to startup formation. These authors find that more departments spanned by the discovery team (which they interpret as coordination costs) is negatively associated with a lower likelihood of licensing (although the effect reverses for a squared term indicating a curvilinear effect). Our matched cross-sectional results do not yield a significant coefficient on the *interdisciplinarity* variable.

When applying the twins methodology, however, the sign of the estimated coefficient on *interdisciplinarity* becomes positive (Table 3, column 7). That is, when a more interdisciplinary team develops a highly similar invention as a less interdisciplinary team, it is more likely to commercialize via startup formation. By controlling for latent commercialization, we take off the table the role of coordination costs and project selection. Having overcome these costs, there are at least two reasons to think that interdisciplinary teams are more likely to commercialize a given discovery. First, a more diverse set of perspectives among the original scientists may improve opportunity recognition because of varied inputs. Baron (2006, p. 17) claims that “opportunity recognition can be enhanced by providing potential entrepreneurs with a very broad range of experience. . . the broader this experience. . . the more likely the entrepreneurs will be to perceive connections between seemingly unrelated events or trends.” Similarly, Shane and Venkataraman (2000) argue that heterogeneity may “give rise to different entrepreneurial conjectures” (p. 220). Second, a more diverse set of scientists may have broader networks than those who all work in the same field (Hills et al. 1997). Networks may amplify the informational advantage mentioned previously, or they may lead to sources of human or financial capital.

Our results regarding discovery team composition while holding constant latent commercializability thus help to reconcile the coordination costs of interdisciplinary work with the potential for enhanced opportunity recognition and resource assembly by a cross-disciplinary team. Our results on heterogeneity (Appendix D) suggest that the predictive role of interdisciplinary discovery teams of academic entrepreneurship is strongest in the United States, in the nonbiotechnology life science sector, and in the pre-2000 time period. The deeper dive into the forms of interdisciplinarity that matter most likewise suggest that the coordination costs of disciplinary-focused researchers are offset by discovery team members who are themselves interdisciplinary.

As in our prior discussion on discovery team composition, however, the interdisciplinarity results

should not be interpreted as causal. In general, future research may delve more deeply into the process of scientific team formation. Boudreau et al. (2017) suggest that there are search frictions associated with the process of finding scientific collaborators. In a field experiment context, they found that randomization in research funding information session colocation among researchers had a substantial (75%) boost in the likelihood that author dyads would submit collaborative proposals. Results like these suggest that a deeper understanding of the antecedents of discovery team formation will be helpful in better understanding how discovery team composition more generally impacts academic entrepreneurship.

6. Discussion and Conclusion

Given interest in translating academic science into commercial products, including via startups, improving our insight into the antecedents of this process is essential. Prior work has yet to account for differences in the inherent commercial potential of scientific discoveries, however, which may result in spurious inferences through omitted variable bias. Based on an algorithmic approach, we assemble a large sample (about 20,000) of scientific codiscoveries, which allows us to hold constant the scientific advance (and therefore addresses the confound of latent commercializability). Compared with a matched cross-sectional empirical strategy that does not address the issue of latent commercializability, we demonstrate that the magnitude and sometimes even the direction of estimated effect can differ. The scientific-twins approach is aimed at holding constant “nature” to focus on the effect of “nurture” or environmental effects, as is the case with human twin studies.

Focusing on two broad classes of mechanisms—resource munificence and discovery team composition—we confirm the importance of both in a cross-sectional analysis of a matched cross-sectional analysis drawn from all academic articles in the WoS from 1955 to 2017 while *not* accounting for latent commercial differences. However, when controlling for these differences via our twin-discovery approach, we no longer find empirical support for the resource munificence view, most notably the effect of local venture capital investment activity. It may be that selection by researchers with a commercial disposition into prominent institutions or resource-rich geographies is a better explanation for existing findings. Regarding discovery team composition, however, we both reaffirm and refine existing findings. In both matched cross-sectional and twin-discovery analyses, we find a strong connection between exposure to peers with entrepreneurial experience. In controlling for latent commercialization, unlike prior literature, we can state that these peer effects are not driven solely by project

selection. Our results also revisit prior findings regarding interdisciplinarity: although in the cross section we find no effect of interdisciplinary, when controlling for latent commercializability, we observe that interdisciplinary teams are in fact more likely to commercialize.

A limitation of our methodology is that we may not capture scientific commercialization by a startup that licenses or otherwise appropriates the discovery *without* involvement from the original scientists. In addition, as previously noted, our results should also not be interpreted as causal, as team composition is of course not randomly determined. One selection effect could be the unobservability of author teams that did not successfully publish their paper. This would impact the possible censoring of observed twin discoveries, especially if the main reason why a given paper is not published is because journal editors decide that the focal paper is not novel given an existing paper already published or accepted for publication in the literature. If author teams of these censored papers are equally distributed by interdisciplinarity and association with star commercializers, this would not present a problem. If, on the other hand, such unobserved paper author teams are much more likely to be uniform with regard to disciplinary background and less likely to have a star commercializer on the author team, then our results may be biased upward. Although we do not think this is likely, the issue illustrates a broader interpretational point associated with our methodology: we take the process generating observed scientific twins as given (and therefore exogenous to our study). As noted in the prior section, our findings suggest a fruitful avenue for future research would be to better understand the antecedents of both discovery team composition as well as the scientific codiscovery. In addition, we believe that there is ample opportunity to examine not just outcomes related to the act of entrepreneurial commercialization itself, but also any number of subsequent venture outcomes and milestones. Doing so would extend our understanding of the lifecycle from scientific advance to commercial impact.

Acknowledgments

The authors are grateful for feedback from Christine Beckman, Kristoph Kleiner, and participants of the Wharton Technology & Innovation Conference; the Global Entrepreneurship & Innovation Conference; the Strategy Science Conference, West Coast Research Symposium at Stanford; the Crete Workshop on Innovation & Creativity; and department seminars at Washington University in St. Louis, Cornell University, and Korea Advanced Institute of Science and Technology. The authors thank Chris Ackerman, Rafael Castro, Andrea Contigiani, and Luming Yang for excellent research assistance, Guan-Cheng Li for data on patent-to-paper

citations, Michael Ewens for USPTO/VentureSource concordance, and Kyle Myers for USPTO/Crunchbase/Small Business Innovation Research concordance. Errors and omissions are ours.

Appendix A. Characteristics of Twin Discoveries

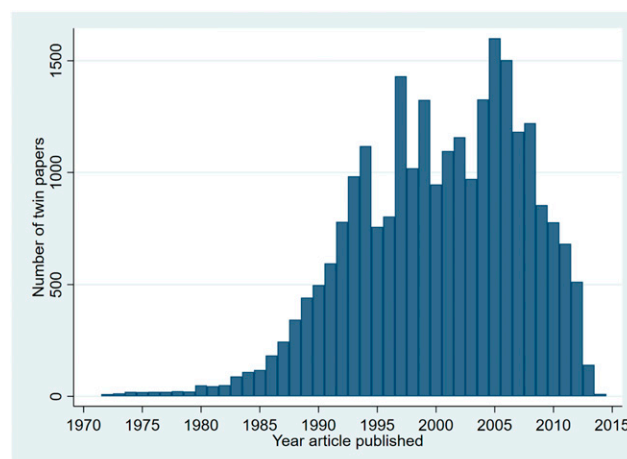

Our 23,851 twin discoveries range from 1973 to 2015 and are from more than 3,000 academic institutions in 106 countries. Figure A.1 shows their temporal distribution. (There may be additional twin discoveries in the distant past, but these are hard to discover because SBIR data are available only since 1983, and patent-to-paper citations are difficult to collect pre-1976 given errors in optical character recognition processing of patent applications. This may also explain why the modal year for a twin discover is somewhat more recent than for the entire Web of Science, 2000 versus 1997.)

Table A.1 shows the distribution of twin discoveries by geography, discipline, and institution. Over half of twin discoveries occur in the United States, followed by Great Britain, Germany, and Japan. When considering pairs of twin papers, one-third of pairs both occur in the United States and 37% of twin papers are in the same country. Panel B details the disciplinary fields of the twin discoveries. The life sciences are responsible for many of the most popular categories of twin discoveries, although physics is the most popular category. Astronomy and astrophysics is also a frequent source of twin discoveries. Finally, panel C tabulates the academic institutions with the most twin discoveries.

Appendix B. Name Overlap and Validation for the Startup Commercialization Outcome Variable

As described in the main text, our algorithm for determining commercialization relies on overlap between the authors of a paper in the Web of Science and either inventors on a patent or the principal investigators on an SBIR award.

Figure A.1. (Color online) Temporal Distribution of Twin Discoveries

We implement name matching for Web of Science authors versus SBIR personnel, removing hyphenation and other punctuation. (We examine the first 30 authors on each paper although some papers have more than 30 authors.) Although full names are available for SBIR and patents, many papers only have the authors' surname and initial(s). If both the author and the SBIR awardee have both initials present but these do not match, a score of zero is assigned. Names lacking first initials are ignored. Otherwise, a match score is assigned through a series of steps. First, we determine whether the surnames match exactly or nearly, where "nearly" indicates that both surnames are more than five characters long and fewer than one-fourth of the characters must be changed to convert one to the other (i.e., Levenshtein distance). Moreover, the surnames must start with the same letter (e.g., "Rogers" and "Bogers" are

not matched). Two names are treated as a preliminary match if the surname meets these criteria and the first initials also match. We want to avoid the situation where the author “J Smith” is assumed to be the same as the SBIR awardee “Jesse Smith,” so we score surnames according to their inverse frequency of appearance in the Web of Science. For instance, surname Smith would be downscaled to near-zero as it is among the most common author names. Surnames that comprise less than 0.007% of all authors (i.e., 2nd percentile) are not downscaled. If only two authors match between the paper and SBIR grant, and both of them represent more than 0.005% of all authors, we conclude that there is no match. Regardless of surname, matches are considered exact if both first and second initials are present for both names and they both match. A similar algorithm is implemented for computing overlap between authors of articles and inventors on patents.

To evaluate whether our algorithm truly captures instances of startup commercialization, we examine a random sample of both types of potential examples of commercialization to seek direct confirmation of our algorithmic approach. Table B.1 shows 5 of the 20 examples of paper-patent pairs we researched, and Table B.2 shows 5 of the 20 examples of SBIR grants. We start by randomly selecting 20 scientific papers drawn from each route of identifying commercialization. For each of these papers, we retrieve the underlying scientific article via Google Scholar searches and record the authors. For Table B.1, we retrieve the associated patent from our algorithmic approach described in the main text via Google Patents (patents.google.com). We record the patent title,

inventors, and assignee. For Table B.2, we retrieve the associated SBIR grants to the focal companies via sbir.gov and record the grant title, funding agency and amount, and the listed principal investigator/business contact. To verify the linkages in both panels between scientific paper and commercialization activity, we conduct web searches in the following manner: we find the overlapping names between paper author and patent inventor or SBIR contact—those are shown in bold in the table. We search the web for the union of the overlapped name(s) and the new venture entity. The final column in both tables provide web links (all accessed in January 2019) providing confirmation of commercialization activity in all ten instances (in the broader sample, we verified 39 of 40 overall cases).

One interesting case is the second entry in Table B.1. We initially had difficulty finding confirmation but then found that one of the author/inventors, Larry Gold, had founded a company, NeXagen, to commercialize his technology, changed the name of the company, and subsequently sold that company to Gilead Sciences. The patent was subsequently reassigned to Gilead Sciences, which is why initially we thought we had failed to find a linkage.

Appendix C. Characteristics of Star Commercializers

Appendix Table C.1 provides additional information on the nature of star entrepreneurial commercializers. Only 0.4% of the more than 73 million authors in the WoS have had one of their discoveries commercialized by a startup. The vast majority of authors whose discoveries are commercialized by startups do so only once (mean = 1.26). Overall, less than 0.01% of all authors are ever stars in this respect.

Table C.1. Descriptive Statistics for Star Entrepreneurial Commercializers

Panel A: Star commercializers vs. all other authors (N: 7,164 vs. 73,923,279)				
	Average nonstar	Average star	Standard deviation	<i>p</i> <
Lifetime number articles	1.639	13.708	0.040	0.000
Average citations per paper	13.179	30.961	0.555	0.000
Number years publishing	0.899	7.432	0.035	0.000
Panel B: Most popular fields for star commercializers				
Field of study	Percent of stars in that field			
Biochemistry and molecular biology	13.2			
Chemistry, multidisciplinary	6.5			
Engineering, electrical and electronic	5.1			
Immunology	4.5			
Physics, applied	4.2			
Oncology	3.9			
Multidisciplinary Sciences	3.6			
Chemistry, medicinal	3.6			
Cardiac and cardiovascular systems	3.3			
Endocrinology and metabolism	2.9			
Panel C: Prevalence of star commercializers among commercialized discoveries				
	Pre-2000	2000 and later		
Biotech	0.27	0.22		
Non-biotechnology life sciences	0.00	0.03		
Non-life sciences	0.06	0.05		

Panel A of Table C.1 compares stars with all other authors in the WoS. Perhaps unsurprisingly, stars have many more articles and citations per article, and they have been publishing longer than non-stars. Panel B details the most popular fields among stars, using 251 fields from the WoS. biochemistry and molecular biology is the most frequent field for entrepreneurial commercialization (13.2% of all stars work primarily in this field), followed by chemistry, electrical and electronic engineering, immunology, and applied physics. Panel C shows the frequency of star involvement in commercialized discoveries by industry and time period.

Appendix D. Geographic, Industry, and Temporal Heterogeneity

In Table D.1, we attempt to understand whether the results from Table 3 are driven by geography, scientific field, or time periods, with the caveat that splitting the sample along these dimensions may yield noisier estimation because of lack of statistical power. Columns 1–3 split the sample of twins into three groups: (1) both twins are in the United States; (2) neither of the twins in the scientific discovery is in the United States; and (3) the scientific discovery contains a twin from the United States and a twin from outside the United States. Most are mixed—that is, in the third category. Twins are somewhat more often commercialized when the discovery teams are interdisciplinary, but only as

long as one of the twins is in the United States. The effect of having a star commercializer on the paper is also strongest within U.S.-only twins. Prior collaboration with a star commercializer appears to play a role primarily for twins where both articles are from outside the United States.

Regarding scientific field, much of our collective empirical knowledge on commercialization draws on the field of biotechnology, perhaps because of data availability reasons, as previously discussed. In column 4, having a star commercializer on the paper predicts commercialization of biotechnology discoveries, but neither interdisciplinarity nor prior association with a star does. Of course, the life sciences are not limited to biotechnology; in column 5, we analyze non-biotechnology papers in life sciences and find that interdisciplinarity plays a key role. Prior association with a star commercializer plays a role as well. Finally, in column 6, we analyze non-life sciences papers, of which there are more than either of the other categories. We find no statistically significant covariates.

Columns 7 and 8 attempt to situate these results temporally, splitting the sample into papers published before and after the year 2000. It appears that interdisciplinarity played a significant role only for papers published in the 20th century. Moreover, we observe a shift from reliance on having a star among the authors of the paper earlier (column 7) to prior association with a star (column 8).

Table D.1. Heterogeneity in Commercialization by Geography, Industry, and Time Period

	Both twins in United States	Neither twin in United States	Only one in United States	Biotechnology	Non- biotechnology life sciences	Not life sciences	Pre-2000	Post-1999

Twin-discovery fixed effects	Yes	Yes	Yes	Yes	Yes	Yes	Yes	Yes

Notes. Observations are articles reporting twin academic discoveries, generated as per the procedure described in Section 3. Columns 1–3 explore geographic variation depending on whether both, neither, or just one of the twins is in the United States. Columns 4–6 subsample the twins data by whether they are from biotechnology, nonbiotechnology life sciences, or outside the life sciences, respectively. Finally, columns 7 and 8 split the sample by time period. All models estimated with OLS; robust standard errors. Mean of the DV = 0.009. Each model includes fixed effects for the twin discovery. Not shown are controls for number of authors, the count of citations from patents to the scientific articles, and whether the article was a twin in multiple discoveries.

* $p < 0.1$; ** $p < 0.05$; *** $p < 0.01$.

Endnotes

¹ We discuss these issues in the next section. As an example of these inference challenges, consider the finding of Stuart and Ding (2006) that prior association with a professor possessing entrepreneurial experience predicts the focal professor also doing so. This could reflect learning about what it means to be an entrepreneur, as typically interpreted in work on peer effects (Nanda and Sørensen 2010). In the case of academic entrepreneurship, however, it could be because of the influence of a mentor on project selection. That is, researchers intentionally select scientific avenues of inquiry with higher commercial potential. Without being able to account for latent commercializability, it is difficult to tease this mechanism apart.

² This empirical strategy also allows us to improve inference by mitigating the possibility of confounding relationships. Latent commercializability can be a confounding factor in the estimated empirical relationship between discovery team composition and entrepreneurial commercialization. In the estimated (not true) equation, regressing startup formation on observed discovery team characteristics confounds whether team characteristics predict a commercializable discovery or predicts startup commercialization. By holding a discovery constant and relating varied discovery team composition to entrepreneurial commercialization, we can tease these effects apart (we thank an anonymous reviewer for this point).

³ Relative to cross-sectional type approaches, other streams of research have also demonstrated that empirical strategies for addressing unobserved variables can overturn conventional results, such as Hsu (2004) in analyzing entrepreneurial affiliation with prominent venture capitalists.

⁴ Of the 23,851 twins identified, multiple adjacent citations were found for 62%. This count of adjacent citations is a lower bound, as we could retrieve only 280,000 of the 1.2M papers where both twins are in the reference list. If it had been possible to inspect all 1.2M papers, we likely would have found multiple adjacent citations for more twins. In Table 5, we drop the twins established via a single adjacent citation, yielding similar results.

⁵ Twin discoveries are not randomly distributed, however, and therefore in our cross-sectional empirical comparisons (which do not control for latent commercializability), we undertake a matching strategy to bring the twin and non-twin samples into better balance along key observable characteristics.

⁶ If the authors of an article have an identical overlap score with the inventors on multiple patents, ties are broken in two steps. First, the PPP closest in time is retained. Second, if two patents in the same year form pairs with the same paper, we further resolve ambiguity via cosine similarity between the abstract of the article and the summary text of the patent.

⁷ For institutions in North America, we also have technology transfer-related variables from the Association of University Technology Managers (AUTM) and compute models limited to institutions where such variables are available. However, because the AUTM data rely on respondent survey responses that are self-reported and because of the limited (domestic) coverage of the data only among some association members, we do not report these models.

⁸ Seventeen were in both categories. This modest overlap probably arises from the specific set of inclusion criteria for the PPP and SBIR measures, as described in Section 3.1. To verify that our measures are capturing what they should, we examine if there are false negatives among the SBIR sample of firms with a patent in which our algorithm should have flagged as a PPP. We start by (exact) matching our sample of SBIR winners with patent assignee names. About half of the SBIR awardees did not have patents. On the subsample that did have a patent, we undertake a series of manual checks to see if we missed any overlaps with the PPP route. We removed any observations with inconsistent geography, time, or individual name information. On the remaining observations, we hand checked a

random 10% sample for misclassifications by inspecting the non-patent references using Google Patents. Through this process, we did not find any misclassifications.

⁹ In some cases, more than one twin paper was matched to the same nontwin paper, so the number of nontwins in panel B of Table 1 is lower than the number of twins.

¹⁰ In unreported results, we estimate the previous equation on the entire WoS, with similar results.

¹¹ In unreported results, we remove fixed effects for the twin discovery and recover results reminiscent of Table 2. In particular, the coefficient on venture capital proximity is positive and precisely estimated.

¹² One difference between the setting of prior studies versus academic scientists is that faculty undertaking entrepreneurial ventures often remain in their positions. For example, Professor Robert Langer, whose research has spawned over 40 startups, never left Massachusetts Institute of Technology; instead, his associates took the lead in commercialization efforts.
